

Debunking Math Myths Regarding Learning Differences, Difficulties, Disabilities

by Donna Curry

The "D" in LD does not stand for Deficit. Therefore, we should not think of students who learn differently as being deficient in some way, although that is often how they have been treated. In fact, even the word "disability" suggests that someone is unable to learn or that he cannot learn what other students can. The reality is that these students can learn; they just do so in ways that are different from the mainstream. In actuality, each of us learns differently, depending on the subject, the way the material is presented, our own personal experiences, and many other variables. Many of our adult learners that are suspected of having learning disabilities may have had poor math experiences that get in the way of efficiently learning in our classes.

No matter how our students learn, or what baggage they bring with them to our adult education classroom, the important thing is that everyone should have the opportunity to receive a high quality education. According to the National Council of Teachers of Mathematics (NCTM), one of the six major guiding principles for school mathematics is access and equity: "An excellent mathematics program requires that all students have access to a high-quality mathematics curriculum, effective teaching and learning, high expectations, and the support and resources needed to maximize their learning potential." [p. 5]

How do we make sure we are being equitable with all of our students? According to the National Research Council (2001), "It is in the best interest of special-needs children to assume that the following principles apply to all children: (a) learning with understanding involves connecting and organizing knowledge; (b) learning builds on what children already know; and (c) formal school instruction should take advantage of children's informal everyday knowledge of mathematics... learning difficulties among special-needs children stem largely from instruction that violates one or more of these principles. Common mistakes in their instruction include (a) not assessing, fostering, or building on their informal knowledge; (b) overly abstract instruction that proceeds too quickly; and (c) instruction that relies on memorizing mathematics by rote" [p. 342]. What is clear is that we need to give all of our students (whether or not they actually have a diagnosis of LD) the opportunity to learn math – and by "learning" we're not talking about computation. (Just because a student can perform a rote calculation does not mean she is using math any more than we would say a student is literate simply because she can decode words.)

There are two myths that seem to get in the way of teachers being able to teach all students to be effective math problem-solvers. First, they may think that LD students are not capable of conceptual understanding. However, recent research on cognitive strengths of dyslexic individuals has shown that they sometimes have strengths in 3-D spatial thinking, connected to strengths in mechanics and complex visualization. Another strength of some individuals with dyslexia is interconnected and narrative reasoning; individuals with dyslexia tend to make unique associations between concepts, and excel in discerning patterns [Lambert, p. 3]. Perhaps one of the challenges that LD students have in traditional math classrooms is that there is too much focus on memorizing disconnected information, rather than focusing on making connections among math concepts.

A second myth about LD students is that they are not capable of developing and using their own strategies; hence, we **have** to show them what to do, model it, and then let them practice it again and again. Most early research studies on LD students had been focused on explicit, direct instruction. When researchers tested whether explicit instruction helped, the answer was yes. Traditionally, this explicit instruction in math often focused on rote procedures. However, there was no research that suggested that direct instruction was the **only** way to teach nor that discovery learning was ineffective. More recent research focused on having students develop their own strategies has shown that students are capable of doing so [Lambert, p. 4]. In fact, having their own strategies rather than trying to remember ones modeled by a teacher eases the strain on students' memory.

To support teachers as they help LD students and their peers develop into strong strategic problem-solvers and build on their strengths, the SABES Mathematics and Adult Numeracy Curriculum & Instruction PD Center has developed a set of workshops on using visual representations in math class. These short courses offer other ways of thinking conceptually and problem-solving as an alternative to memorizing procedures. After all, it is not necessary for college, for life, or for work to be able to solve problems with a particular procedure. What is necessary is to be able to make sense of problems and get reasonable answers and that is something that all of our students can learn. We can help teachers to help their students do just that.

The three workshops are all part of a series entitled *Using Visuals to Develop Conceptual Understanding*. Our Center can bring any of these workshops directly to your region. Simply contact us at donnac@zwi.net and we'll work with you to make it happen.

On the following pages are examples to illustrate how visual representations such as area models, number lines, and Singapore strips can help any student who has struggled with memorizing procedures.

Using the area model to multiply with decimals - Example: 0.8×0.4

Hmmm. Do I have to line up decimals for this problem? And, where in the world does the decimal go at the end??

Let's see. I break a whole into rows and columns of 10 tenths each so I have 100 hundredths. If I shade 8 tenths, I know that's what I'm starting with. Then I'm figuring out what 4 tenths of that amount is. I can count and actually see how many little hundredths I have. I can see that the intersection of the blue and yellow (which makes green) is the answer to the question *What is 0.8×0.4 ?*

Using the number line to divide with fractions – Example: $4\frac{1}{2} \div \frac{3}{4}$

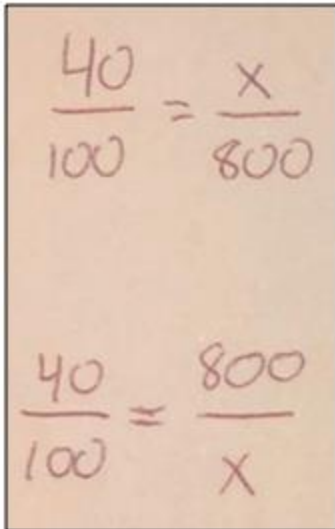

$$4\frac{1}{2} = \frac{9}{2}$$
$$\frac{9}{2} \div \frac{3}{4}$$
$$\frac{9}{2} \times \frac{4}{3}$$
$$\frac{36}{6}$$
$$6$$

Well...Is this the type of problem where I have to flip and multiply? If so, do I flip the first or second number? What was the rule? PEMDAS? KFC? Or is this where I do the cross product thingy?

This is asking for how many $\frac{3}{4}$ can I fit into $4\frac{1}{2}$? One way I could do this is to actually see it on a number line.

Using bar models (tape diagrams, Singapore strips) with percents – Example: Suong spends 40% of her monthly income on rent. Her rent is \$800. How much does she make per month?

Handwritten equations on a piece of paper:

$$\frac{40}{100} = \frac{x}{800}$$
$$\frac{40}{100} = \frac{800}{x}$$

Let's see. Am I looking for the part? The whole? I think I have to change the percent to a decimal and then put it over 100 . . . I think. But then what?

Hmmm. Do I have to find the part or whole? Let me visualize the problem so I can clearly see what I'm looking for. . . now I see that \$800 is 2 out of 5 parts (or 40%) of all of Suong's income. I can figure out her entire income now in different ways.

Suong's total monthly income or 100%

What she spends on rent: \$800 or 40%
